REGRESSION AND ANALYSIS OF VARIANCE FOR GENETICISTS

REGRESSION

(image from http://www.geneart.org/genome-title.htm)
MATRICES

1. Rectangular array of numbers

\[
\begin{bmatrix}
3 & 5 & 7 & 8 \\
1 & 2 & 3 & 7
\end{bmatrix} = A_{2\times4}
\]

Symbol - cap letter \( A, B, C \)

2. Vectors

3. Elements \( a_{ij} \)

4. Operations

(a) Addition or subtraction
   Element by element

(b) Multiplication

Vector \((1, 3, -5, 1)\)

\[
\begin{bmatrix}
2 \\
0 \\
3 \\
-2
\end{bmatrix} = 2 + 0 - 15 - 2
\]

= -15
Matrices

\[
\begin{bmatrix}
1 & 3 & 5 \\
-2 & -1 & 2
\end{bmatrix}
\begin{bmatrix}
2 & 3 \\
0 & 5 \\
1 & -2
\end{bmatrix}
= 
\begin{bmatrix}
7 & 8 \\
-2 & -15
\end{bmatrix}
\]

Note: In general, \(BA\) does not equal \(AB\)
(may have different dimensions)

(c) Transpose \(A'\)

Note: \((AB)' = (B') (A')\)

(d) Scalar Multiplication

\[3 \begin{bmatrix}
1 & 2 \\
-2 & 3
\end{bmatrix}
= 
\begin{bmatrix}
3 & 6 \\
-6 & 9
\end{bmatrix}\]

5. Identity Matrix \(I\)

\[
I = 
\begin{bmatrix}
1 & 0 & 0 \\
0 & 1 & 0 \\
0 & 0 & 1
\end{bmatrix}
\]

\(IA = AI = A\) for \(A_{3\times3}\)

\(IB = B\) for \(B_{3\timesC}\)

\(CI = C\) for \(C_{r\times3}\)
6. Rank and dependence

\[ \mathbf{A} = \begin{bmatrix} 1 & 1 & 1 \\ 3 & 1 & 5 \\ 2 & 3 & 1 \end{bmatrix} \text{ columns} = \begin{bmatrix} 1 \\ 3 \\ 2 \end{bmatrix}, \begin{bmatrix} 1 \\ 1 \\ 3 \end{bmatrix}, \text{ and } \begin{bmatrix} 1 \\ 5 \end{bmatrix} \]

Note: \(2\mathbf{C}_1 - \mathbf{C}_2 - \mathbf{C}_3 = \Phi\) where \(\Phi\) is a column of 0's.

We say that \(\mathbf{C}_1, \mathbf{C}_2,\) and \(\mathbf{C}_3\) are linearly dependent.

In general: \(k\) columns \(\mathbf{C}_1, \mathbf{C}_2, \ldots, \mathbf{C}_k\) are dependent if there exist scalars \(\lambda_1, \lambda_2, \ldots, \lambda_k\) such that

(1) \(\lambda_1\mathbf{C}_1 + \lambda_2\mathbf{C}_2 + \ldots + \lambda_k\mathbf{C}_k = \Phi\)

and

(2) At least one of the \(\lambda\)'s is not 0.

If the \(k\) columns are not dependent we call them linearly independent. The combination of columns in (1) is called a linear combination, a phrase we will often use. Thus, \(k\) columns are linearly independent if the only linear combination of them which will produce the zero vector is the linear combination with all \(\lambda\)'s 0. Often we will collect the \(\lambda\)'s together in a vector \(\Lambda\).

The rank of a matrix is the maximum number of linearly independent columns which can be selected from the columns of the matrix. Thus the rank of \(\mathbf{A}\) is two. Notice that if the rank
of a matrix is 1, then there is one column such that all other columns are direct multiples.

For any matrix $X$, the rank of $X$ is the same as the rank of $X'X$. The row rank of any matrix is always equal to the column rank.

7. Inverse of a matrix.

Symbol: $A^{-1}$

The inverse of an $n \times n$ matrix $A$ is an $n \times n$ matrix $B$ such that $AB = I$. Such a matrix $B$ will exist only if $A$ is of rank $n$. In this case it is also true that $BA = I$.

Example:

$$A = \begin{bmatrix} 1 & -1 & 1 \\ 2 & 1 & 0 \\ 3 & 1 & 1 \end{bmatrix} \quad A^{-1} = \begin{bmatrix} +0.5 & 1 & -0.5 \\ -1.0 & -1 & 1.0 \\ -0.5 & -2 & 1.5 \end{bmatrix}$$

(Check by multiplication.)
Solving equations

\[ \begin{align*}
\begin{bmatrix}
1 & -1 & 1 \\
2 & 1 & 0 \\
3 & 1 & 1
\end{bmatrix}
\begin{bmatrix}
b_0 \\
b_1 \\
b_2
\end{bmatrix}
&=
\begin{bmatrix}
2 \\
7 \\
-5
\end{bmatrix}
\end{align*}\]

\[ \begin{bmatrix}
b_0 \\
b_1 \\
b_2
\end{bmatrix}
=
\begin{bmatrix}
+0.5 & 1 & -0.5 \\
-1.0 & -1 & 1.0 \\
-0.5 & -2 & 1.5
\end{bmatrix}
\begin{bmatrix}
2 \\
7 \\
-5
\end{bmatrix}
=
\begin{bmatrix}
10.5 \\
-14.0 \\
-22.5
\end{bmatrix}\]

\[ Ab = c \Rightarrow b = A^{-1} c \]

For a 2 \times 2 matrix only we have the formula:

\[ \begin{bmatrix}
a & b \\
c & d
\end{bmatrix}^{-1}
=
\frac{1}{ad - bc}
\begin{bmatrix}
d & -b \\
-c & a
\end{bmatrix}\]

Note: if \( A \) and \( B \) are square matrices then \( A^{-1} B^{-1} = (BA)^{-1} \)
**RANDOM VECTORS**

We have described a *univariate* random variable like weight $W$ by writing

$$W \sim N(150, 100)$$

We might also measure height in inches $H$ and have

$$H \sim N(68, 16)$$

Now the above tells us nothing about how the two variables height and weight *covary*. The *covariance* between $H$ and $W$ tells us how weight depends on height. If we know an individual is taller than the mean 68, would we predict that his weight will exceed the mean 150? If so we are claiming a positive covariance between height and weight. Formally, recall that the variance of weights is defined as an *expected value*, namely

$$\text{variance} \ (W) = E \{(W - 150)^2 \}.$$  

The covariance between $W$ and $H$ is defined as

$$\text{cov} \ (W, H) = E \{(W - 150) \ (H - 68) \}.$$  

Suppose the covariance is $\text{cov}(W, H) = 30$. We put this all together as
In general we write

\[ Y \sim MVN(\mu, V) \]

where \( Y \) is a vector with \( i^{th} \) element \( Y_i \), \( \mu \) is a vector with \( i^{th} \) element \( \mu_i \) and \( V \) is a matrix whose \( ij^{th} \) element is the covariance between \( Y_i \) and \( Y_j \).

******

****** Fact: If \( A \) and \( B \) are matrices of constants and \( Y \) is a random vector with \( MVN(\mu, V) \), then

\[ AY + B \sim MVN(A\mu + B, AVA') \]

Example:

\[ Y \sim MVN \begin{bmatrix} 4 & 8 & 5 & 0 \\ 6 & 5 & 12 & 4 \\ 10 & 0 & 4 & 9 \end{bmatrix} \]

(1) Find the distribution of \( Z = Y_1 - Y_2 + Y_3 \).

(2) Let \( W = Y_1 - 3Y_2 + 2Y_3 \). Find the joint distribution of \( Z \) and \( W \).
Flower example

Multivariate Normal Computations

I grow flowers with certain characteristics:

\[ Y_1 = \text{Head diameter} \sim N(4,8) \]
\[ Y_2 = \text{Stem length} \sim N(6,12) \]
\[ Y_3 = \text{Root length} \sim N(10,9) \]

What about covariances? To fill in the picture, here is the complete distribution:

\[
\begin{pmatrix}
Y_1 \\
Y_2 \\
Y_3
\end{pmatrix}
\sim
\text{MVN}
\begin{pmatrix}
4 \\
6 \\
10
\end{pmatrix},
\begin{pmatrix}
8 & 5 & 0 \\
5 & 12 & 4 \\
0 & 4 & 9
\end{pmatrix}
\]

Now 2 people compete to buy these flowers from me. They offer prices for each flower related to its dimensions. The prices, \( Z_1 \) and \( Z_2 \), offered by the two buyers are:

\[
\begin{pmatrix}
Z_1 \\
Z_2
\end{pmatrix} = \begin{pmatrix}
1Y_1 - 1Y_2 + 1Y_3 \\
1Y_1 - 3Y_2 + 2Y_3
\end{pmatrix}
\]

Which is the better offer in terms of mean? Which has the smaller variance? How often will \( Z_2 \) exceed \( Z_1 \)?

All of these questions and more can be answered if we know the joint distribution of \((Z_1, Z_2)\). Calling this vector \( Z \), we want to relate it to the vector \((Y_1, Y_2, Y_3)'\) by expressing it as

\[
Z = AY + b
\]

as in our notes. Multiply this out to check that it
works:

\[
\text{vector } Z = \begin{pmatrix} Z_1 \\ Z_2 \end{pmatrix} = \begin{pmatrix} 1 & -1 & 1 \\ 1 & -3 & 2 \end{pmatrix} \begin{pmatrix} Y_1 \\ Y_2 \\ Y_3 \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \end{pmatrix}
\]

This equation tells us, for example, what prices would be offered for a flower with \(Y_1 = 5\), \(Y_2 = 4\), and \(Y_3 = 14\). We find

\[
\text{vector } Z = Z = \begin{pmatrix} Z_1 \\ Z_2 \end{pmatrix} = \begin{pmatrix} 1 & -1 & 1 \\ 1 & -3 & 2 \end{pmatrix} \begin{pmatrix} 5 \\ 4 \\ 14 \end{pmatrix} = \begin{pmatrix} 15 \\ 21 \end{pmatrix}
\]

So for this flower with its longer than average roots and shorter than average stem, we would be better off going with the second person.

What happens on average? Our formula for the mean of vector \(Z\) tells us that

\[
\text{mean of } Z = \begin{pmatrix} \mu_1 \\ \mu_2 \end{pmatrix} = \begin{pmatrix} 1 & -1 & 1 \\ 1 & -3 & 2 \end{pmatrix} \begin{pmatrix} 4 \\ 6 \\ 10 \end{pmatrix} = \begin{pmatrix} 8 \\ 6 \end{pmatrix}
\]

We are better off going with the first buyer who will give us 8 cents on average. Which buyer has the smaller variance in price? What is the covariance between the prices? To answer this, we compute the variance-covariance matrix of the price vector \(Z\) from the variance-covariance matrix \(V\) that goes with the \(Y\) vector (we compute \(AVA'\)): 

Dickey
Not only is the first buyer offering more on average, his price will vary less than that of the second buyer given the kind of variation I have in my population of flowers. I also see that the two prices have a correlation \( r = \frac{22}{\sqrt{11 \times 74}} \).

Finally, what is the distribution of the price difference \( D = Z_2 - Z_1 \) and what is the probability that \( D \) will be positive, that is, what proportion of the time will the flower dimensions be such that I regret my decision to deal with the first buyer?

We see that \( D = (-1 1)(Z_1, Z_2)' \) so the mean of \( D \) is \((-1 1)(8 6)' = -2\) and the variance is

\[
\begin{pmatrix} -1 & 1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} 11 & 22 \\ 22 & 74 \end{pmatrix} \begin{pmatrix} -1 \\ 1 \end{pmatrix} = 41
\]

So the probability that \( D \) is greater than 0 is the probability that a standard normal \( Z \) variable exceeds \( (0-(-2))/6.4031 = 0.31 \). Note that since the variance is 41, then 6.4031 is the standard deviation (the square root of 41). From the normal table

\[
\Pr\{Z > 0.31\} = .3783
\]

so we regret our decision about 38% of the time.

One more note: Usually we do not KNOW these parameters. From a sample, we would estimate them.
**REGRESSION - HAND CALCULATION**

Review of "hand" calculations:

<table>
<thead>
<tr>
<th>DATA</th>
<th>X</th>
<th>4</th>
<th>7</th>
<th>5</th>
<th>4</th>
<th>Y</th>
<th>5</th>
<th>7</th>
<th>6</th>

</tr>
</thead>
<tbody>
<tr>
<td>X-\bar{X}</td>
<td></td>
<td>-1</td>
<td>1</td>
<td>-1</td>
<td>1</td>
<td>\bar{Y}-\bar{Y}</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>(X-\bar{X})^2</td>
<td></td>
<td>1</td>
<td>4</td>
<td>1</td>
<td>1</td>
<td>(Y-\bar{Y})^2</td>
<td>0</td>
<td>0</td>
<td>2</td>
<td>2</td>
</tr>
<tr>
<td>(X-\bar{X})(Y-\bar{Y})</td>
<td></td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>2</td>
<td>\Sigma(X_i-\bar{X})^2</td>
<td>0</td>
<td>6</td>
<td>3</td>
<td>3</td>
</tr>
<tr>
<td>\Sigma(Y_i-\bar{Y})^2</td>
<td></td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>2</td>
<td>\Sigma(X_i-\bar{X})(Y_i-\bar{Y})</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

\[
slope = b = \frac{\Sigma(X_i-\bar{X})(Y_i-\bar{Y})}{\Sigma(X_i-\bar{X})^2} = \frac{3}{6} = 0.5
\]

intercept = \(a = \bar{Y} - b\bar{X} = 6 - (0.5)(5) = 3.5\)

True slope \(\beta\). Recall that \(b \sim N(\beta, \sigma^2/\Sigma(X_i - \bar{X})^2)\).

True intercept \(\alpha\).

Recall that \(a \sim N\left(\alpha, \sigma^2 \left[\frac{1/n + \bar{X}^2}{\Sigma(X_i - \bar{X})^2}\right]\right)\)
Estimate $\sigma^2$ by $s^2 = \frac{\text{(total SSq - regn SSq)}}{\text{df}}$

Regn. SSq = $\frac{\left(\sum(X_i-\bar{X})(Y_i-\bar{Y})\right)^2}{\sum(X_i-\bar{X})^2} = 3 * \frac{3}{6} = 1.5$

Total SSq = 2

$\text{df} = n - 2 = 4 - 2 = 2$

so $s^2 = \text{MSE} = \frac{(2 - 1.5)}{2} = 0.25$

Estimated variance of $a$ is $0.25(1/4 + 25/6) = 1.1042$

Estimated variance of $b$ is $0.25/6 = 0.041667$

Notice that hand computations gave no indication of covariance.

EXAMPLES:

Test for no relationship between $Y$ and $X$.

\[ H_0: \beta = 0, \quad t = \frac{b - 0}{\text{std. err. of } b} = .5 / \sqrt{.041667} \]

Give 95% confidence interval for mean $Y$ at $X = 6$.

$3.5 + .5 (6) = 6.5 = \text{prediction}$

add and subtract $t$ times std. err. of prediction

std. err. of prediction = $\sqrt{\frac{1}{n} + (6- \bar{X})^2/\sum(X_i-\bar{X})^2} \times 0.25$

Give 95% prediction interval for individual $Y$ at $X = 6$.

same prediction, 6.5

std. err. of prediction = $\sqrt{\frac{1 + 1}{n} + (6- \bar{X})^2/\sum(X_i-\bar{X})^2} \times 0.25$
Example of a regression:

\[ 78.4098 \]  
\[ 48 \]  
\[ 200.181 \] 

Dickey
Discussion of correlation coefficients:

We define the (population) correlation between two variables as the covariance divided by the square root of the product of the variances. For height and weight as just given, \( \rho = 30/\sqrt{100*16} = 0.75 \). Now suppose we take \( n = 103 \) people and measure their height \( H_i \) and weight \( W_i \). As usual, we can estimate variances as

\[
S^2_W = \frac{\Sigma(W_i - \bar{W})^2}{(n - 1)} \quad \text{and} \quad S^2_H = \frac{\Sigma(H_i - \bar{H})^2}{(n - 1)}.
\]

The covariance is estimated as

\[
S_{WH} = \frac{\Sigma(W_i - \bar{W})(H_i - \bar{H})}{(n - 1)}.
\]

Now these are just estimates of the true values so let us assume we get, say,

\[
S^2_W = 125, \quad S^2_H = 20, \quad \text{and} \quad S_{WH} = 40.
\]

Our estimated covariance matrix is then

\[
\hat{V} = \begin{bmatrix} 125 & 40 \\ 40 & 20 \end{bmatrix}
\]

and we compute a sample estimate, \( r \), of \( \rho \) as

\[
r = \frac{40}{\sqrt{125*20}} = 0.8.
\]
Notice that

\[ r^2 = \frac{\sum(W_i - \bar{W})(H_i - \bar{H})^2}{\sum(W_i - \bar{W})^2 \sum(H_i - \bar{H})^2} = \text{regression SS/total SS} \]

from a regression of either H on W or of W on H. Thus we have explained 64% of the variability in W by regressing it on H.

A test that \( \rho = 0 \) is just the t-test on the coefficient in the regression of W on H (or equivalently H on W). To test any other hypothesis like \( H_0: \rho = 0.5 \) or to put a confidence interval around \( r \), Fisher's transformation to Z is used. We define

\[ Z_r = 0.5 \ln((1 + r)/(1 - r)) \]

and define \( Z_\rho \) similarly. Now approximately we have

\[ Z_r \sim N(Z_\rho, 1/(n - 3)) \]

Thus we get \( Z_{0.8} = 1.09861 \) so

\[ 1.09861 - 0.196 \]

and

\[ 1.09861 + 0.196 \]

are the lower and upper confidence bounds for \( Z_\rho \).

Converting from \( Z_\rho \) to \( \rho \) we get \( 0.71 \leq \rho \leq 0.86 \). Tables can be used to do the conversions or simply do them on a hand calculator.
REGRESSION IN MATRIX FRAMEWORK

The equations: (Henceforth intercept is $\beta_0$, slope is $\beta_1$)

$$
\begin{align*}
5 &= \beta_0 + 4 \beta_1 + e_1 \\
7 &= \beta_0 + 7 \beta_1 + e_2 \\
6 &= \beta_0 + 5 \beta_1 + e_3 \\
6 &= \beta_0 + 4 \beta_1 + e_4
\end{align*}
$$

Matrix form:

$$
\begin{bmatrix}
5 \\
7 \\
6 \\
6
\end{bmatrix}
= 
\begin{bmatrix}
1 & 4 \\
1 & 7 \\
1 & 5 \\
1 & 4
\end{bmatrix}
\begin{bmatrix}
\beta_0 \\
\beta_1
\end{bmatrix}
+ 
\begin{bmatrix}
e_1 \\
e_2 \\
e_3 \\
e_4
\end{bmatrix}
\Rightarrow 
Y = X\beta + e
$$

Estimate $\beta$ by $b$ such that $(Y - Xb)'(Y - Xb)$ is minimized.

Note: this is the sum of squares of residuals $Y - Xb$.

Using calculus we can show the sum of squares is minimized by solving the following “normal equations.”

********

******** $(X'X)b = X'Y$ i.e. $b = (X'X)^{-1}(X'Y)$

********

THIS FORMULA IS IMPORTANT

Dickey
Our little example:

\[
X'X = \begin{bmatrix}
4 & 20 \\
20 & 106
\end{bmatrix} \Rightarrow (X'X)^{-1} = \frac{1}{424-400} \begin{bmatrix}
106 & -20 \\
-20 & 4
\end{bmatrix}
\]

We find the solution

\[
b = \begin{bmatrix}
4.4167 & -0.8333 \\
-0.8333 & 0.1667
\end{bmatrix} \begin{bmatrix}
24 \\
123
\end{bmatrix} = \begin{bmatrix}
3.5 \\
0.5
\end{bmatrix}
\]

Now let's relate the vector of estimated parameters (\(b\)) to the vector of actual parameters (\(\beta\)). We have

\[
b = (X'X)^{-1} (X'Y) = (X'X)^{-1} (X'(X\beta + e)) = \beta + (X'X)^{-1} (X'e).
\]

The difference between \(b\) and \(\beta\) is \(b - \beta = (X'X)^{-1}(X'e)\).

Results:

(1) \(b\) is an unbiased estimate of \(\beta\).
(2) The variance-covariance matrix of \( \mathbf{b} \) (\( \mathbf{V}_b \)) is related to that of \( \mathbf{e} \) (\( \mathbf{V}_e \)) by the formula (using our \( \mathbf{AVA}' \) with \( \mathbf{A} = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}' \))

\[
\mathbf{V}_b = ((\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{V}_e \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1})
\]

(3) Let us assume that all the \( e \)'s have the same variance, have mean 0, and are uncorrelated. That means

\[
\mathbf{V}_e = \sigma^2 \mathbf{I}
\]

and after all the smoke clears, we obtain the crucial formula

\[
\mathbf{V}_b = \text{var}(\mathbf{b}) = (\mathbf{X}'\mathbf{X})^{-1} \sigma^2
\]

**ESTIMATION OF VARIANCE OF \( e \)**

(1) Sum of squared residuals

(sum of squared errors, SSE)

\[ Y - X\mathbf{b} \text{ vector of residuals} \]

For any vector \( \mathbf{a} \), \( \mathbf{a}' \mathbf{a} \) is sum of squared elements
\[ \text{SSE} = (Y - \mathbf{Xb})' (Y - \mathbf{Xb}) \]

\[ = Y'Y \quad \text{Uncorr. Total SSq} - b'X'Y \quad \text{Uncorr. Regn. SSq} \]

\[ = (Y'Y - n\bar{y}^2) - (b'X'Y - n\bar{y}^2) \quad \text{Corrected total SSq} \quad \text{Corrected Regn. SSq} \]

(2) Error df = n - 2 (2 = one intercept + one slope)

\[ \text{MSE} = \frac{\text{SSE}}{\text{df}} \]

(3) For our little example, check this against the previous computation.

(4) Error degrees of freedom will always give degrees of freedom for \( t \) statistics.

Example (Continued.)

Variance-covariance matrix of parameter estimates

\[ \mathbf{V}_b = \begin{bmatrix} 4.4167 & -0.8333 \\ -0.8333 & 0.1667 \end{bmatrix} (0.25) = \begin{bmatrix} 1.1042 & -0.2083 \\ -0.2083 & 0.0417 \end{bmatrix} \]

(1) Test that slope is 0: \( t = \frac{0.5}{\sqrt{0.0417}} \)

\[ (2 \text{ degrees of freedom}) \]

\[ = \frac{0.5}{0.2041} = 2.45 \]
(2) Test that intercept is 0: \( t = \frac{3.5}{\sqrt{1.1042}} = 3.33 \)

(2 degrees of freedom)

(3) Estimate mean value of \( Y \) at \( X = 6 \) and give 95% confidence interval.

Estimate is \( 3.5 + 0.5 \times 6 = 6.5 \)

We are estimating \( \beta_0 + 6 \beta_1 = (1, 6) \begin{bmatrix} \beta_0 \\ \beta_1 \end{bmatrix} \)

Our estimate is \( (1, 6)b = b_0 + 6b_1 = 3.5 + (6)(0.5) = 6.5 \)

Letting \( \Lambda' = (1, 6) \) we now want the variance of \( \Lambda'b \) but we know how to get that: (AVA' result where \( A \) is now the row \( \Lambda' \))

\[
\text{Var} (\Lambda'b) = \Lambda' V_b \Lambda = (1, 6) \begin{bmatrix} 1.1042 & -0.2083 \\ -0.2083 & 0.0417 \end{bmatrix} \begin{bmatrix} 1 \\ 6 \end{bmatrix} = 0.1042
\]

95% confidence interval : \( 6.5 \pm t \times \sqrt{0.1042} \)

(4) Predict future individual value at \( X = 6 \)

Individual will differ from mean by a deviation with variance estimated by MSE = 0.25. Any future individual value at \( X = 6 \) is equal to mean at \( X = 6 \) plus deviation. Thus the variance is the sum of the variances of these two parts, namely, \( 0.25 + 0.1042 = 0.3542 \). Notice that the prediction interval
for an individual future value is wider than the corresponding confidence interval for the mean. We get, for our little example,

\[ 6.5 \pm t \times \sqrt{0.3542} \]

Since \( t \) has 2 d.f. we obtain \( t = 4.30 \) and thus

- Confidence interval (5.11, 7.89)
- Prediction interval (3.94, 9.06)

Example: You are in charge of predicting wheat yields from rainfall through July for your country so that you can place import quotas in early August. You have historic data on rain and yields. Which of the above formulas do you use and why?

Example: An industrial quality control expert takes 200 hourly measurements on an industrial furnace which is under control and finds that a 95% confidence interval for the mean temperature is (500.35, 531.36). As a result he tells management that the process should be declared out of control whenever hourly measurements fall outside this interval and, of course, is later fired for incompetence. (Why and what should he have done?)
**SUMMARY OF REGRESSION FORMULAS**

Model: \( Y = X \beta + e \) where \( e \sim \text{MVN}(0, \sigma^2 I) \)

Normal Equations: \( X'Xb = X'Y \)

Solution: \( b = (X'X)^{-1} (X'Y) \) provided \( X'X \) is full rank

Estimate of variance-covariance matrix of \( b \): \( (X'X)^{-1} \text{MSE} \)

Predictions for observed \( Y \)'s is: vector \( Xb \).
We write \( \hat{Y} = Xb \) (\(^\wedge\) denotes predictor).

Residuals: \( = Y - Xb \)
SSE = \( (Y - Xb)' (Y - Xb) = Y'Y - b'X'Y = \)
\( \text{total SSq} - \text{regn. SSq}. \)

\( \text{df} = n \text{ minus rank of } X \text{ matrix.} \)
(Usually, rank = number of columns in \( X \), i.e. full rank.)

Prediction of future \( Y \)'s at some configuration of \( X \)'s:
Prediction written as \( \hat{Y} = \Lambda'b \) where \( \Lambda' = (1, \text{X-values}) \). In our example \( \Lambda' = (1, 6) \).
Variances of predictions:

for mean at configuration of $X$'s in $\Lambda'$:

$$(\Lambda'(X'X)^{-1} \Lambda) \text{ MSE}$$

for individual at configuration of $X$'s in $\Lambda$:

$$(\Lambda'(X'X)^{-1} \Lambda + 1) \text{ MSE}$$

ANOVA (Column of 1's and $k$ other columns.)

<td>8</td>
<td>79</td>
</tr>
<tr>
<td>114</td>
<td>20</td>
<td>98</td>
</tr>
<tr>
<td>102</td>
<td>15</td>
<td>76</td>
</tr>
</tbody>
</table>

ANOVA (Grade on IQ)

<table>
<thead>
<tr>
<th>Source</th>
<th>df</th>
<th>SSq</th>
<th>Mn Sq</th>
<th>F</th>
</tr>
</thead>
<tbody>
<tr>
<td>IQ</td>
<td>1</td>
<td>15.9393</td>
<td>15.9393</td>
<td>0.153</td>
</tr>
<tr>
<td>Error</td>
<td>6</td>
<td>625.935</td>
<td>104.32</td>
<td></td>
</tr>
</tbody>
</table>

It appears that IQ has nothing to do with grade, but we did not look at study time. Looking at the multiple regression we get

ANOVA (Grade on IQ, Study Time)

<table>
<thead>
<tr>
<th>Source</th>
<th>df</th>
<th>SSq</th>
<th>Mn Sq</th>
<th>F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>2</td>
<td>596.12</td>
<td>298.06</td>
<td>32.57</td>
</tr>
<tr>
<td>Error</td>
<td>5</td>
<td>45.76</td>
<td>9.15</td>
<td></td>
</tr>
</tbody>
</table>
From this regression we also can get

\[
(X'X)^{-1} = \begin{bmatrix}
28.8985 & -2261 & -2242 \\
-2261 & .0018 & .0011 \\
-2242 & .0011 & .0076
\end{bmatrix}
\]

1. To test H0: Coefficient on IQ is 0 (Note: calculations done with extra decimal accuracy.)

   (a) Using t-test \( t = \frac{0.47}{\sqrt{0.0018}\times9.15} = 3.64 \)

   (b) Using type II F-test, \( F = \frac{121.24/9.15}{9.15} = 13.25 = t^2 \).

Note: The type II sum of squares is defined by setting \( t^2 = F \). This means that type II SSq = b\(b/c \) where b is the coefficient being tested and c is the diagonal element of \((X'X)^{-1}\) which corresponds to b. We have \((0.47)(0.47)/0.0018 = 121.24\).

2. Estimate the mean grade for the population of all potential students with IQ = 113 and study time = 14 hours.
(a) Write this estimate as $\Lambda'b$ where $\Lambda' = (1, 113, 14)$.

(b) Variance of this is $\Lambda'(X'X)^{-1}\Lambda'MSE = 1.303$.

(c) Prediction is $\Lambda'b = 83.64$.

(d) To get confidence interval,

$$83.64 \pm 2.571 \sqrt{1.303}$$

(e) Interval $(80.71, 86.57)$

3. Estimate grade for individual with 113 IQ and 14 hours study time.

$$83.64 \pm 2.571 \sqrt{1.303} + 9.15$$

$$=(75.33, 91.95)$$

4. What percent of grade variability is explained by IQ, STUDY?

$R^2 = \frac{\text{(corrected regn. SSQ)}}{\text{(corrected total SSq)}} = \frac{596.12}{641.88} = 93\%$

5. Notes: When a new column is added to a regression, all the coefficients and their t-statistics can change. The t's could go from significance to insignificance or vice-versa.

The exception to the above case is when the added column of $X$ is orthogonal to the original columns. This means
that the new $X'X$ has the old $X'X$ in the upper left corner, the sum of squares of the new column as the bottom right element, and all other elements 0.

Suggested exercise: Regress GRADE on TIME IQ IQ_ST where IQ_ST = IQ*STUDY. The IQ_ST variable could be created in your data step. For the regression of GRADE on TIME and IQ, use the option /I in PROC REG. This will output the $(X'X)^{-1}$ matrix.

"Missing Y trick": Rerun this example adding a row 113 14 . at the end of the dataset. The dot implies a missing value. Use the statement MODEL GRADE = IQ STUDY / P CLM; Compare to part 2 above. Rerun again with CLI instead of CLM. Compare to part 3 above. Was the extra data row used in computing the regression coefficients? Let's try some of this:

OPTIONS LS = 80 NODATE;
DATA GRADES; INPUT IQ STUDY GRADE @@;
   IQ_ST = IQ*STUDY; DATALINES;
   105 10 75 110 12 79 120 6 68 116 13 85
   122 16 91 130 8 79 114 20 98 102 15 76
;  
PROC REG;
   MODEL GRADE = IQ STUDY IQ_ST/SS1 SS2;
Proc Plot;
   PLOT STUDY*IQ = '*' / VPOS = 35;
DATA extra;
   INPUT IQ STUDY GRADE;
Datalines;
113 14 .
; DATA BOTH;
  SET GRADES EXTRA;
PROC REG;
  MODEL GRADE = IQ STUDY/P CLM;
RUN;

Dickey
Discussion of the interaction model. We call the product 
IQ * S = IQ * STUDY an “interaction” term. Our model is 

\[ \hat{G} = 72.21 - 0.13 \text{IQ} - 4.11 \text{S} + 0.0531 \text{IQ} \times \text{S}. \]

Now if IQ = 100 we get 

\[ \hat{G} = (72.21 - 13.1) + (-4.11 + 5.31)\text{S} \]

and if IQ = 120 we get 

\[ \hat{G} = (72.21 - 15.7) + (-4.11 + 6.37)\text{S}. \]

Thus we expect an extra hour of study to increase the 
grade by 1.20 points for someone with IQ = 100 and by 2.26 
points for someone with IQ = 120 if we use this interaction 
model. Since the interaction is not significant, we may want to 
go back to the simpler “main effects” model.

Suppose we measure IQ in deviations from 100 and 
STUDY in deviations from 8. What happens to the coefficients 
and t-tests in the interaction model? How about the main effects 
model?

**POLYNOMIAL REGRESSION**

Polynomial means form

$$Y = \beta_0 + \beta_1 X + \beta_2 X^2 + \cdots + \beta_k X^k$$

EXAMPLE: We expose cells to radiation $X$ times (dose) and observe $Y =$ number of mutations. We see that up to a point, increasing the dose increases mutations but beyond that point, mutations begin to decrease. Our goal is to model mutations as a function of dose.

DATA ($Y =$ MUTATIONS, $X =$ DOSE )

<table>
<thead>
<tr>

</tbody>
</table>

Note: In the second half of this course you will learn a technique called the "analysis of variance" or ANOVA. The ANOVA essentially fits a mutation mean for each dose. The ANOVA error sum of squares, 24, is just the pooled (summed) SSq from within each treatment group. The predictions (group
means) are not constrained in any way. The mean $Y$ is 7 and the sum of squares of the $Y$ deviations, the "total sum of squares" is $(3-7)^2+(5-7)^2+\ldots+(4-7)^2 = 78$ with $10-1 = 9$ degrees of freedom (DF). ANOVA breaks this 78 into the unexplained error sum of squares 24 plus a part $78-24 = 54$ that is attributed to the variation among the "treatment" means (i.e. to dose):

ANOVA

<table>
<thead>
<tr>
<th>Source</th>
<th>df</th>
<th>SSq</th>
<th>Mn Sq</th>
<th>F</th>
<th>Pr&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dose</td>
<td>4</td>
<td>54</td>
<td>13.5</td>
<td>2.81</td>
<td>0.1436</td>
</tr>
<tr>
<td>Error</td>
<td>5</td>
<td>24</td>
<td>4.8</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The job can be done easily in PROC GLM.

PROC GLM; CLASS X; MODEL Y = X;

Try this and you will get a printout like this:
(this is the computerized way of getting the ANOVA table).

GENERAL LINEAR MODELS PROCEDURE
CLASS LEVEL INFORMATION

<table>
<thead>
<tr>
<th>CLASS</th>
<th>LEVELS</th>
<th>VALUES</th>
</tr>
</thead>
<tbody>
<tr>
<td>DOSE</td>
<td>5</td>
<td>2 3 4 5 6</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>SOURCE</th>
<th>DF</th>
<th>SSq</th>
<th>Mn Sq</th>
<th>F</th>
</tr>
</thead>
<tbody>
<tr>
<td>MODEL</td>
<td>4</td>
<td>54</td>
<td>13.5</td>
<td>2.81</td>
</tr>
<tr>
<td>ERROR</td>
<td>5</td>
<td>24</td>
<td>4.8</td>
<td></td>
</tr>
</tbody>
</table>
Next we will fit a quadratic to the data (forcing predicted values to lie on a parabola) and observe how much the fit deteriorates.

DATA A;  INPUT Y  X  XSQ;
CARDS;
   3   2   4
   5   2   4
   7   3   9
  10   4  16
   8   4  16
  12   4  16
   5   5  25
  10   5  25
   6   5  25
   4   6  36
PROC REG; MODEL Y = X XSQ;

The output contains the following information:

<table>
<thead>
<tr>
<th>SOURCE</th>
<th>DF</th>
<th>SSq</th>
<th>Mn Sq</th>
<th>F</th>
<th>Pr&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>MODEL</td>

<td>7</td>
<td>28.58</td>
<td>4.08</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

| PARAMETER | ESTIMATE | T      | PR>|T| |
|-----------|----------|--------|------|
| INTERCEPT | -12.5280 | -2.19  | .0644 |
| X         | 11.0311  | 3.47   | .0104 |
| XSQ       | -1.3975  | -3.40  | .0115 |

The ANOVA, which basically fits group means to the 5 treatment groups, has increased the regression sum of squares over that of the quadratic, from 49.4161 (2df) to 54 (4df). Later, we will show that the ANOVA (means) model is like a "full model" and the quadratic like a "reduced model."

The test which asks if the regression does as well as the unconstrained means ANOVA in fitting the data is called a "lack of fit F test." We compute

\[
F^2_{\frac{5}{2}} = \frac{[(54 - 49.4161)/2]}{4.8} = 0.4775
\]

Since F is insignificant (2 and 5 df) we say there is no significant lack of fit. We conclude that a model forcing mutation to be a quadratic in dose seems to explain mutation as well as a model in which unconstrained means are fit to the data.
To show that the F test is a full versus reduced model F test, I will show that the ANOVA approach is the same as fitting the highest degree polynomial possible to the data. Since there are $m = 5$ values of $X$, the highest possible degree is $m - 1 = 4$. Thus we issue the commands:

```
PROC GLM; MODEL Y = X  X*X  X*X*X  X*X*X*X;
```

Notice that no CLASS statement was used and that PROC GLM will actually compute the powers of $X$ for you. We get:

<table>
<thead>
<tr>
<th>SOURCE</th>
<th>DF</th>
<th>SSq</th>
<th>Mn Sq</th>
<th>F</th>
</tr>
</thead>
<tbody>
<tr>
<td>MODEL</td>
<td>4</td>
<td>54</td>
<td>13.5</td>
<td>2.81</td>
</tr>
<tr>
<td>ERROR</td>
<td>5</td>
<td>24</td>
<td>4.8</td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>SOURCE</th>
<th>TYPE I SS</th>
<th>TYPE II SS</th>
</tr>
</thead>
<tbody>
<tr>
<td>X</td>
<td>2.25</td>
<td>2.93</td>
</tr>
<tr>
<td>X*X</td>
<td>47.17</td>
<td>3.57</td>
</tr>
<tr>
<td>X<em>X</em>X</td>
<td>0.45</td>
<td>3.98</td>
</tr>
<tr>
<td>X<em>X</em>X*X</td>
<td>4.13</td>
<td>4.13</td>
</tr>
</tbody>
</table>

| PARAMETER ESTIMATE | T       | PR > |T| |
|--------------------|---------|-------|
| INTERCEPT           | 82      | 0.73  | 0.4962 |
| X                  | -100    | -0.78 | 0.4698 |
| X*X                | 44.5    | 0.86  | 0.4273 |
| X*X*X              | -8      | -0.91 | 0.4041 |
| X*X*X*X            | 0.5     | 0.93  | 0.5388 |
Using the TYPE I \( SSq \) we compute the lack of fit \( F \) as:

\[
F = [(0.45 + 4.13)/2] / 4.8 = 0.4771
\]

the same as before and we thus see that the lack of fit statistic is testing for the powers of \( X \) up to the highest possible power you can fit to the data. The only reason that there is an error term left to test this against is the fact that some \( X \)'s had repeated \( Y \)'s with them and so the highest possible degree, \( m - 1 = 4 \), is less than the total degrees of freedom \( n - 1 = 9 \) leaving 5 degrees of freedom (with sum of squares 24) for “pure error.”

As before, we see that it is incorrect and dangerous to make a conclusion about the joint significance of all the coefficients taken together if we look only at the \( t \) statistics.

**RESPONSE SURFACE METHODOLOGY**

In a *response surface* model, a response is some function (usually quadratic) of one or more control variables. Here is an example (of yields in a chemical reaction) analyzed on the computer:

```
DATA REACT; INPUT YIELD PH TEMP@@;
PSQ = PH**2; TSQ = TEMP**2; PT = PH*TEMP;
CARDS;
  90 5 60 100 5 80 95 5 100 105 5.5 80
  100 6 60 130 6 80 125 6 100 140 6.5 80
  135 7 60 142 7 80 126 7 100
;```

Dickey
PROC PRINT;
PROC REG;  MODEL YIELD = PH TEMP PSQ TSQ PT/P;
PROC RSREG;  MODEL YIELD = PH TEMP;

Note the use of @@ to keep SAS from going to a new line for each observation read. If we omitted @@ we would get only 2 observations in our data set. You can use the "missing Y trick" to get SAS to compute a 95% prediction interval for the yield of a future reaction at PH 6.3 and temperature 92 degrees. This involves inputting the X values 6.3 and 92 and a missing value "." for Y. SAS cannot use this observation to determine the regression coefficients (it does not know the Y value) but once these are determined, it can predict since it knows the X values.

</thead>
<tbody>
<tr>
<td>Eigenvalues</td>
</tr>
<tr>
<td>-2.618751</td>
</tr>
<tr>
<td>-11.432192</td>
</tr>
</tbody>
</table>

Stationary point is a maximum.

Example:
\[ \hat{Y} = -382 + 70.62 P + 5.65 T - 2.98 P^2 - 0.028 T^2 - 0.175 PT \]

- Critical point:  P = 9.7517, T= 71.2998

- \[ \hat{Y} = 163.23 + \]
\[ (P-9.7517) (T-71.2998) \begin{pmatrix} -2.9800 & -0.0875 \\ -0.0875 & -0.0280 \end{pmatrix} \begin{pmatrix} P - 9.7517 \\ T - 71.2998 \end{pmatrix} \]
\[ = 163.23 + \mathbf{X}'\mathbf{A}\mathbf{X} \]
\[
\begin{pmatrix}
-2.98 & -0.0875 \\
-0.0875 & -0.028
\end{pmatrix}
= A = ZLZ' =
\]

\[
\begin{pmatrix}
-0.0296 & 0.9996 \\
0.9996 & 0.0296
\end{pmatrix}
\begin{pmatrix}
-0.0251 & 0 \\
0 & 2.9837
\end{pmatrix}
\begin{pmatrix}
-0.0296 & 0.9996 \\
0.9996 & 0.0296
\end{pmatrix}
\]

\[
\hat{Y} = 163.23 + X'LZ'X = 163.23 + W'LW =
163.23 + (-0.0251) w_1^2 + (-2.984) w_2^2
\]

\[
(w_1, w_2) = (0,0) = \text{critical point, response is 163.23. Any movement away from critical point reduces response.}
\]

**Additional Points:** Critical point may be max, min, or saddle point. It may be nowhere near experimental region. Ridge Analysis (not ridge regression) takes spheres of ever increasing radius around some point in the experimental region. On each sphere, coordinates of response maximizer (minimizer) are computed resulting in a path of maximum increase (decrease). PROC RSREG has a RIDGE statement to do this. Again eigenvalues are involved.

**DUMMY VARIABLES**

Y = time to get my results from the lab  
X = 1 if it's lab A, 0 if it's lab B:

<table>
<thead>
<tr>
<th>X</th>
<th>0</th>
<th>1</th>
<th>1</th>

<td>23</td>
</tr>
</tbody>
</table>
### Data Analysis

Total sum of squares \[ \sum_{i=1}^{8}(Y_i - \bar{Y})^2 = 16+9+4+\ldots+1 = 84 \]

X variance \[ \frac{1}{7}\sum_{i=1}^{8}(X_i - \bar{X})^2/7 = 2/7 \]

Covariance: \[ \left[\frac{(-\frac{1}{2})(-4)+\ldots+(\frac{1}{2})(1)}{7}\right] = 11/7 \]

\[ b = \frac{11}{2} = 5.5 \quad a = 22 - 5.5(\frac{1}{2}) = 19.25 \]

\[ \hat{Y} = 19.25 + 5.5X = \begin{cases} 19.25 & \text{if } X = 0 \text{ (lab B)} \\ 24.75 & \text{if } X = 1 \text{ (lab A)} \end{cases} \]

slope = 5.5 is "shift" = difference of 2 levels.

Lab A: \( \hat{\gamma} = (13.75 + 1(4.5)) + .5*\text{Num} \)
Lab B: \( \hat{\gamma} = (13.75 + 0(4.5)) + .5*\text{Num} \)
COVARIANCE ANALYSIS

The example above results in two parallel lines. This kind of analysis is often referred to as analysis of covariance or ANCOVA. The ANOVA model is written:

\[ Y_{ij} = \mu + \alpha_i + e_{ij} \]

where \( \alpha_1 \) is the lab A effect and \( \alpha_2 \) is the lab B effect.

Now write a model which incorporates both the treatment effect and the linear effect of number of samples analyzed, \( N \), as displayed in the graph. We write

\[ Y_{ij} = \mu + \alpha_i + \beta^*(N_{ij} - \overline{N}_{..}) + e_{ij} \]

where \( \overline{N}_{..} \) is the sample mean of the “covariate” (number of samples analyzed in our case). You can fit this model using either the covariate \( N_{ij} \) or the deviations \( (N_{ij} - \overline{N}_{..}) \) of the covariate from its sample mean.

Finally, we see that at the average number of samples \( \overline{N}_{..} = 22 \) (or \( N - \overline{N}_{..} = 0 \) if you used deviations as your covariate), the predicted values are 13.75 + 0 + 0.5(22) = 24.75 and 13.75 + 4.5 + 0.5(22) = 29.25. This illustrates the fact that a covariance analysis simply adjusts all the analysis times to the levels they would have had if both labs had analyzed \( \overline{N}_{..} = 22 \) samples. These are often called adjusted treatment means.
A covariance example:

3 technicians. Each decodes 6 strands.

Decoding time is response, depends on strand length.

Want to compare technicians.

data gen;

9.13 + 0  + (0.0182 + 0)*Length  tech 3

Are lines parallel?  <=>  Do we need Ltech1, Ltech2?

\[
F = \frac{[(1.773+3.012)/2]}{15.987} = 0.15
\]
Not significant, parallel lines OK.

or...

Parallel Lines Model  \(\text{SSE} = 196.63\)
Arbitrary Lines Model \(\text{SSE} = 191.85\)
\[
F = \frac{[(196.63-191.85)/2]}{15.987} = 0.15
\]
Because the lines can be taken to be parallel, computing adjusted treatment means for the three technicians makes sense. These are estimates of the average decoding times for the three technicians, if all strands had been the same length (namely the average observed strand length $\overline{L} = 907.8$)

\[
\begin{align*}
9.92 - .64 \quad &+0.0173 \times 907.8 = 24.98 \quad \text{tech 1} \\
9.92 + 11.405 \quad &+0.0173 \times 907.8 = 37.03 \quad \text{tech 2} \\
9.92 + 0 \quad &+0.0173 \times 907.8 = 25.62 \quad \text{tech 3}
\end{align*}
\]

Count data

1. Estimating, testing proportions

100 seeds, 45 germinate. We estimate probability $p$ that a plant will germinate to be 0.45 for this population. Is a 50% germination rate a reasonable possibility?

$$\text{Pr\{45 or less germinate in 100 trials if } p=0.5 \text{ \} = ????}$$

**Binomial:**

- $n$ independent trials
- Each trial success or failure
- $p =$ probability of success same on every trial
- $X =$ observed number of successes in $n$ trials

$$\text{Pr\{X=r\} = n!/[r!(n-r)!] \ p^r \ (1-p)^{(n-r)}$$

0! = 1, 1! = 1, 2! = 2*1 = 2, 3! = 3*2*1 = 6, 4! = 4*3*2*1 = 24 etc.
**Logistic Regression**

Idea: \( p = \text{probability of germinating} = \text{function of some variables (maybe temperature, moisture, or both).} \)

Example:

* Normal residuals ?
* Reasonable predicted probabilities? 1.0558? -0.0172 ?

Better idea: Map 0<p<1 into \( L = ln( \frac{p}{1-p} ) \) then model

\[ L = \alpha + \beta(\text{temperature}) + e \]

or

\[ L = \alpha + \beta(\text{temperature}-70) \]
"Likelihood" = probability of sample = p(1-p)ppp(1-p)p ...p Use p for germinated, 1-p for not germinated.

Substitute $p = e^L/(1+e^L)$, $1 - p = 1/(1+e^L)$ and $L = \alpha + \beta X$

"Maximum Likelihood Estimates"

Likelihood =

$$\left[ e^{\alpha + \beta(70-70)}/(1 + e^{\alpha + \beta(70-70)}) \right] \left[ e^{\alpha + \beta(73-70)}/(1 + e^{\alpha + \beta(73-70)}) \right] \cdots \left[ 1/(1 + e^{\alpha + \beta(75-70)}) \right] = f(\alpha, \beta).$$

Graph $f(\alpha, \beta)$ vs. $(\alpha, \beta)$ and find values of $(\alpha, \beta)$ that maximize.

Theory also gives standard errors (large sample approximations). Use PROC LOGISTIC, PROC GENMOD, or PROC CATMOD in SAS. We get

$$Pr\{\text{Germinate}\} = e^{0.4961 + 0.1821X}/(1+e^{0.4961 + 0.1821X})$$

where $X=$temperature-70.

Plot of P*TEMP. Legend: A = 1 obs, B = 2 obs, etc.
Plot of Y*TEMP. Symbol is value of Y.
**Likelihood Ratio Chi-Square**

Small contingency table

\[
\begin{array}{ccc}
3 & 3 & (6) \\
5 & 2 & (7) \\
8 & 5 & [13]
\end{array}
\]

--- Probabilities are \( \begin{pmatrix} p_{11} & p_{12} \\ p_{21} & p_{22} \end{pmatrix} \)

Likelihood is some constant times

\[
(p_{11})^{n_{11}} (p_{12})^{n_{12}} (p_{21})^{n_{21}} (p_{22})^{n_{22}}
\]

where we must have these ps summing to 1 so that

\[
p_{22} = 1 - p_{11} - p_{12} - p_{21}.
\]

The values of these ps that maximize the likelihood are the same values that maximize the logarithm of the likelihood, namely

\[
n_{11} \ln(p_{11}) + \ldots + n_{22} \ln(1 - p_{11} - p_{12} - p_{21})
\]

and taking the derivatives with respect to each of the three unconstrained ps we have

\[
n_{ij}/p_{ij} = n_{22}/(1 - p_{11} - p_{12} - p_{21})
\]

and if we then solve these 3 equations ( \((i,j) = (1,1), (1,2), (2,1)\) ) we get estimates

\[
\hat{p}_{ij} = n_{ij} / n..
\]

Dickey
so we have $3/13$, $3/13$, $5/13$, and $2/13$ which we then plug into the log likelihood function to get

$$-2 \log(\text{Likelihood}) = C -2\left[3 \ln(3/13) + 3 \ln(3/13) + 5 \ln(5/13) + 2 \ln(2/13) \right]$$

which is $C + 34.638368$ where $C$ is some constant.

Suppose $p_{11} = p_r p_c$ etc. where $p_r$ and $p_c$ are probabilities of being in the first row and of being in the first column respectively. This would be suggested by the independence hypothesis. Then the likelihood is proportional to

$$(p_r p_c)^{n_{11}} (p_r (1-p_c))^{n_{12}} ((1-p_r) p_c)^{n_{21}} ((1-p_r) (1-p_c))^{n_{22}}$$

Taking logs and differentiating we have

$$\hat{p}_r = 6/13 \text{ and } \hat{p}_c = 8/13$$

and $-2 \log(\text{Likelihood}) = C + 35.268067$. The difference in $-2 \log(\text{Likelihood})$ from the full and reduced models has approximately a Chi-square distribution with degrees of freedom equal to the difference in the number of unrestricted parameters. The difference, 0.6297, has 1 df and is the likelihood ratio Chi-square on the printout.

<tr>
<td>Two-sided Pr &lt;= P</td>
<td>0.5921</td>
</tr>
</tbody>
</table>

Sample Size = 13

Notice the warning. The cell counts are not high enough for our usual Chi-square or the likelihood ratio Chi-square test statistics to have close to a \( \chi^2 \) distribution (both are only \textit{approximately} Chi-square in \textit{large} samples).

One approach to this is to use Fisher's exact test. How many tables are more extreme than this one? First, what do we mean by "extreme"? We expect \( 48/13 = 3.7 \) unaltered plants to have no damage but we observe less (3). If we insist on preserving the row and column totals, what other tables could we get with even less unaltered plants that show no damage?

\[
\begin{array}{cc}
2 & 4 \\
6 & 1 \\
\end{array} \quad (P=.08158) \quad \text{and} \quad \begin{array}{cc}
1 & 5 \\
7 & 0 \\
\end{array} \quad (P=.004662)
\]

are even more extreme. Fisher suggested assigning hypergeometric probabilities (as shown) to these tables. Using \( n_{ij} \) to denote the count in row i and column j, \( n_{i.} \) to denote the total row i count, \( n_{.j} \) to denote the total column j count and \( n_{..} \) for
the total count (13) the hypergeometric probability for the original table, for example, is

\[
P = \frac{n_{11}! \cdot n_{21}! \cdot n_{12}! \cdot n_{22}!}{n_{11}! \cdot n_{12}! \cdot n_{21}! \cdot n_{22}! \cdot n_{..}!} = \frac{6! \cdot 7! \cdot 8! \cdot 5!}{3! \cdot 3! \cdot 5! \cdot 2! \cdot 13!} = .3263 \text{ for } \begin{array}{cc} 3 & 3 \\ 5 & 2 \end{array}
\]

so that \(.3263 + .08158 + .00466 = .4126 = \text{left sided Fisher exact P-value on printout.}\)

Note: The "usual Chi-Square" is \(\sum_{\text{all cells}} \frac{(O_i - E_i)^2}{E_i}\) and its degrees of freedom number is \((r-1)(c-1)\) for a table with \(r\) rows and \(c\) columns. \(E_i\) is the expected number for cell \(i\) and \(O_i\) the observed. \(E_i\) is \((\text{row total})(\text{column total})/\text{(grand total)}\) so for upper left cell \(E_i\) is \((6)(8)/13\).
